STEROLS 1. CHOLESTEROL AND CHOLESTEROL ESTERS

STRUCTURE, OCCURRENCE, BIOCHEMISTRY AND ANALYSIS

1. Cholesterol – Structure, Occurrence, Physical Properties and Function

In animal tissues, cholesterol (cholest-5-en-3β-ol) is by far the most abundant member of a family of polycyclic compounds known as sterols (see also our web pages on plant sterols, oxysterols, etc.). It can also be described as a polyisoprenoid or a triterpene because of its biosynthetic origin. It was first recognized as a component of gallstones as long ago as 1770, while the great French lipid chemist Chevreul isolated it as a single pure substance in 1815. However, it was well into the 20th century before the structure was fully defined by the German Chemist Heinrich Wieland, who received the Nobel Prize in Chemistry for his work in 1927, the first of many so honoured for research on cholesterol and its metabolism.

In essence, it consists of a tetracyclic cyclopenta[a]phenanthrene structure with an iso-octyl side chain at carbon 17. The four rings (A, B, C, D) have trans ring junctions, and the side chain and two methyl groups (C18 and C19) are at an angle to the rings above the plane with β stereochemistry (as for the hydroxyl group on C-3 also). There is a double bond between carbons 5 and 6. Thus, the molecule has a rigid planar four-ring nucleus with a flexible tail. There are two recognized numbering systems in use - one originally described by Fieser and Fieser in 1959 and a second by IUPAC-IUB in 1989; the first appears to be preferred by many current authors.

Cholesterol has vital structural roles in membranes and in lipid metabolism in general. It is a biosynthetic precursor of bile acids, vitamin D and steroid hormones (glucocorticoids, oestrogens, progesterones, androgens and aldosterone). In addition, it contributes to the development and working of the central nervous system, and it has major functions in signal transduction and sperm development. It is found in covalent linkage to specific membrane proteins or proteolipids ('hedgehog' proteins), which have vital functions in embryonic development. However, because plasma cholesterol levels can be a major contributory factor to atherogenesis, media coverage has created what has been termed a 'cholesterophobia' in the population at large.

Cholesterol is a ubiquitous component of all animal tissues (and of some fungi), where much of it is located in the membranes, although it is not evenly distributed. The highest proportion of unesterified cholesterol is in the plasma membrane (roughly 30-50% of the lipid in the membrane or 60-80% of the cholesterol in the cell), while mitochondria and the endoplasmic reticulum have very low cholesterol contents, and the Golgi contains an intermediate amount. Cholesterol is also enriched in early and recycling endosomes, but not in late endosomes. It may surprise some to learn that the brain contains more cholesterol than any other organ, where it comprises roughly a quarter of the total free cholesterol in the human body. Of all the organic constituents of blood, only glucose is present in a higher molar concentration than cholesterol. It occurs in the free form, esterified to long-chain fatty acids (cholesterol esters), and in other covalent and non-covalent
linkages in animal tissues, including the plasma **lipoproteins**. In plants, it tends to be a minor component only of a complex mixture of structurally related **phytosterols**, although there are exceptions, but it is nevertheless importance as a precursor of some plant hormones.

Animals in general synthesise a high proportion of their cholesterol requirement, but they can also ingest and absorb appreciable amounts in their diets. On the other hand, many invertebrates, including insects, crustaceans and some molluscs cannot synthesise cholesterol and must receive it from the diet, although some species are able to convert plant sterols such as β-sitosterol to cholesterol. Spiny lobsters must obtain exogenous cholesterol to produce essential sex hormones. Similarly, it must be supplied from exogenous sources to the primitive nematode *Caenorhabditis elegans*, where it does not appear to have a major role in membrane structure, but rather some ill-defined signalling functions controlling development. Prokaryotes lack cholesterol entirely, apart from a few species that acquire it from eukaryotic hosts.

It is generally believed that the main function of cholesterol is to modulate the fluidity of membranes by interacting with their complex lipid components, specifically the phospholipids such as phosphatidylcholine and sphingomyelin. As an amphiphilic molecule, cholesterol is able to intercalate between phospholipids in lipid bilayers, spanning about half a bilayer. In its three-dimensional structure, it is in essence a planar molecule that can interact on both sides. The tetracyclic ring structure is compact and very rigid. In addition, the location of the hydroxyl group facilitates the orientation of the molecule in a membrane bilayer, while the positions of the methyl groups appear to maximize interactions with other lipid constituents.

![](image)

The α-face of the cholesterol nucleus (facing down) is 'smooth' and can make good contact with the saturated fatty-acyl chains of phospholipids down to about their tenth methylene group; the β-face (facing up) is made 'rough' by the projection of methyl groups from carbons 10 and 13. The interaction is mainly via van der Waals and hydrophobic forces with a contribution from hydrogen bonding of the cholesterol hydroxyl group to the polar head group and interfacial regions of the phospholipids, especially sphingomyelin. Indeed, there is evidence that cholesterol forms stoichiometric complexes with the saturated fatty acyl groups of sphingomyelin and to a lesser extent of phosphatidylcholine. Intercalated cholesterol may also disrupt electrostatic interactions between the ionic phosphocholine head groups of nearby membrane phospholipids, leading to increased mobility of the head groups.

Experiments with mutant cell lines and specific inhibitors of cholesterol biosynthesis suggest that an equatorial hydroxyl group at C-3 of sterols is essential for the growth of mammalian cells. The Δ5 double bond ensures that the molecule adopts a planar conformation, and this feature also appears to be essential for cell growth, as is the flexible iso-octyl side-chain. The C-18 methyl group is crucial for the proper orientation of the sterol. While plant sterols appear to be able to substitute for cholesterol in supporting many of the bulk properties of membranes in mammalian cells, cholesterol is essential for other purposes.

In the absence of cholesterol, a membrane composed of unsaturated lipids is in a fluid state that is characterized by a substantial degree of lipid chain disorder, i.e. it constitutes a **liquid-disordered** phase. The function of cholesterol is to increase the degree of order (cohesion and packing) in membranes, leading to formation of a **liquid-ordered** phase. In contrast, it renders bilayers composed of more saturated lipids, which would otherwise be in a solid gel state, more fluid. Thus, cholesterol is able to promote and stabilize a liquid-ordered phase over a substantial range of
temperatures and sterol concentrations. Further, high cholesterol concentrations in membranes reduce their passive permeability to solutes. These effects permit the fine-tuning of membrane lipid composition, organization and function.

Cholesterol also has a key role in the lateral organization of membranes and their free volume distribution, factors permitting more intimate protein-cholesterol interactions that may regulate the activities of many membrane proteins. Some membrane proteins bind strongly to cholesterol, including some that are involved in cellular cholesterol homeostasis or trafficking and contain a conserved region termed the 'sterol-sensing domain'. In addition, cholesterol forms a well-defined and essential association with the sphingolipids in the formation of the membrane sub-domains known as rafts, which are so important in the function of cells. It appears that the synthesis of cholesterol and of sphingolipids, especially sphingomyelin, is regulated co-ordinately to satisfy the requirements of membrane composition and function. The interaction of cholesterol with ceramides is essential for the barrier function of the skin.

In comparison to other lipids, cholesterol can flip rapidly between the leaflets in a bilayer, and the trans-bilayer distribution of cholesterol in some biological membranes is uncertain. While some models propose that cholesterol is on the outer leaflet, other studies suggest that most of the sterol is in the inner leaflet of human erythrocytes, for example. This fact is important in that cholesterol promotes negative curvature of membranes and may be a significant factor in bringing about membrane fusion as in the process of exocytosis.

There is increasing evidence that cholesterol has a more intimate interaction with certain proteins in membranes, especially G protein-coupled receptors. For example, it is essential for the stability and function of the β2-adrenergic receptor, rhodopsin and the (Na⁺-K⁺)-ATPase.

2. Cholesterol Biosynthesis

Cholesterol biosynthesis involves a highly complex series of at least 25 different enzymatic reactions, which were unravelled in large measure in the laboratories of Konrad Bloch and Fyodor Lynen, who received the Nobel Prize for their work on the topic in 1964. When the various regulatory, transport and genetic studies of more recent years are taken into account, it is obvious that this is a subject that cannot be treated in depth here. The bare bones of mechanistic aspects are therefore delineated, which with the references detailed below should serve as a guide to further study.

The first steps involve the synthesis of the important intermediate mevalonic acid from acetyl-CoA and acetoacetyl-CoA, both of which are in fact derived from acetate, in two enzymatic steps.
The acetyl-CoA precursor is in the cytosol as is the first enzyme, hydroxymethyl-glutaryl(HMG)-CoA synthase. The second enzyme HMG-CoA reductase is a particularly important control point, and is widely regarded as the rate-limiting step in the overall synthesis of sterols, and its activity is regulated by several factors including a cycle of phosphorylation-dephosphorylation. This and subsequent enzymes are membrane-bound and are located in the endoplasmic reticulum. The enzyme HMG-CoA reductase is among the targets inhibited by the drugs known as ‘statins’, so that patients must then obtain much of their cholesterol from the diet via the circulation.

The next sequence of reactions involves first the phosphorylation of mevalonic acid by a mevalonate kinase to form the 5-monophosphate ester, followed by a further phosphorylation to yield an unstable pyrophosphate, which is rapidly decarboxylated to produce 5-isopentenyl pyrophosphoric acid. An isomerase converts part of the latter to 3,3-dimethylallylpyrophosphoric acid.

5-Isopentenyl pyrophosphate is a nucleophile, but the isomerized product is electrophilic. In the first step in the third series of reactions, 5-isopentenyl pyrophosphate and 3,3-dimethylallylpyrophosphate condense readily with the elimination of pyrophosphoric acid to form the monoterpenoid derivative geranylpyrophosphate.
This reacts with another molecule of 5-isopentenyl pyrophosphate to produce the sesquiterpene derivative (C_{15}) farnesylpyrophosphate, two molecules of which are condensed to yield presqualene pyrophosphate. This is reduced by NADPH to produce a further key intermediate squalene. Both of the last steps are catalysed by the enzyme squalene synthase, which regulates the flow of metabolites into either the sterol or non-sterol pathways.

In the next important series of reactions, squalene is first oxidized by a squalene monoxygenase to squalene 2,3-epoxide, which undergoes cyclization catalysed by the enzyme squalene epoxide lanosterol-cyclase to form the first steroidal intermediate lanosterol (or cycloartenol en route to phytosterols in photosynthetic organisms). In this remarkable reaction, there is a series of concerted 1,2-methyl group and hydride shifts along the chain of the squalene molecule to bring about the formation of the four rings. No intermediate compounds have been found. This is believed to be one of the most complex single enzymatic reactions ever to have been identified, although the enzyme involved is only 90 kDa in size. Again, the reaction takes place in the endoplasmic reticulum, but a cytosolic protein, sterol carrier protein 1, is required to bind squalene in an appropriate orientation, in the presence of the cofactors phosphatidylserine and flavin adenine dinucleotide (FAD).

In subsequent steps, lanosterol is converted to cholesterol by a series of demethylations, desaturations, isomerizations and reductions. Demethylation reactions produce zymosterol as an intermediate, and this is converted to cholesterol via a series of intermediates, all of which have been characterized, and by at least two pathways that differ in the order of the various reactions, mainly at the point at which the Δ24 double bond is reduced. Perhaps surprisingly, a number of elements in the pathways have to be established definitively, and both desmosterol and 7-dehydrocholesterol may be immediate precursors of cholesterol.

Synthesis occurs mainly in the liver, although the brain, peripheral nervous system and skin synthesise their own considerable supplies. Cholesterol is exported from the liver and transported to other tissues in the form of low-density lipoproteins (LDL) for uptake via specific receptors. In animals, cells can obtain the cholesterol they require either from the diet via the circulating LDL, or they can synthesise it themselves as outlined above. Cholesterol biosynthesis is highly regulated with rates of synthesis varying over hundreds of fold depending on the availability of an external source of cholesterol. Cholesterol homeostasis in general requires the actions of a complex web of enzymes, transport proteins, and membrane-bound transcription factors, i.e. specific proteins within cells are able to sense the existing concentration of cholesterol and control the levels via the synthesis of specific proteins. In addition to the liver, the intestines play a major part in cholesterol
homeostasis via absorption, synthesis and fecal excretion. Cholesterol metabolism in the brain is discussed in the webpage on oxysterols.

Any cholesterol in membranes in excess of the stoichiometric requirement can escape back readily into the cell, where it may serve as a feedback signal to down-regulate cholesterol accumulation. Some of this ‘active’ cholesterol is converted to the relatively inert storage form, i.e. cholesterol esters, and some is used for steroidogenesis. In peripheral tissues, excess cholesterol is exported to high-density lipoproteins (HDL) and returned to the liver.

Although HMG-CoA reductase is a key enzyme in the regulation of cholesterol biosynthesis, many other factors are involved. For example, the regulatory element-binding proteins (mainly SREBP-1c and SREBP-2), which contain an N-terminal membrane domain and a C-terminal regulatory domain, are also essential to the maintenance of cholesterol homeostasis. Each is an inactive precursor, which is inserted into the endoplasmic reticulum, where it can encounter an escort protein termed SREBP cleavage-activating protein (SCAP), which is the cellular cholesterol sensor. When the latter recognizes that cellular cholesterol levels are inadequate, it binds to the regulatory domain of SREBP. The SCAP-SREBP complex then moves to the Golgi, where two specific proteases (designated site-1 and site-2 proteases) cleave the SREBP enabling the C-terminal regulatory domain to enter the nucleus. There it activates a transcription factor, which stimulates the expression of the genes coding for the LDL receptor and for the key enzyme in cholesterol biosynthesis, HMG-CoA reductase. This in turn stimulates the rate of cholesterol uptake and synthesis. Conversely, when cellular cholesterol levels are higher, the SCAP fails to bind to SREBP and uptake and synthesis of cholesterol are not enhanced.

Further regulation of cholesterol biosynthesis is exerted by sterol intermediates in cholesterol biosynthesis and by side-chain oxysterols, such as 24-, 25- and 27-hydroxycholesterol, which can suppress the activation of SREBP by binding to an oxysterol-sensing protein in the endoplasmic reticulum or by direct effects on the biosynthetic and transport enzymes. Also, they control cholesterol homeostasis via transcriptional pathways (see our webpage on oxysterols).

However, many other factors are involved in maintaining within precise limits the large differences in cholesterol concentrations among the various membranes and organelles in cells. These include other regulatory proteins, and mechanisms that can involve either vesicle formation or non-vesicular pathways that utilize specific transport proteins, for example the so-called ‘ABC
transporters’. It is noteworthy that ceramide down-regulates cholesterol synthesis – another link between cholesterol and sphingolipid metabolism.

### 3. Cholesterol Catabolism

Cholesterol is not readily biodegradable so does not serve as a fuel for animal tissues. Only the liver possesses the enzymes to degrade significant amounts, and then via pathways that do not lead to energy production. Cholesterol and oxidized metabolites (oxysterols) are transferred back from peripheral tissues in lipoprotein complexes to the liver for catabolism by conversion to oxysterols and bile acids. The latter are exported into the intestines to aid digestion and leading to some loss that is essential for cholesterol homeostasis (see the web-pages on oxysterols, bile acids and lipoproteins). Until recently, it was believed that approximately 90% of cholesterol elimination from the body occurred via bile acids in humans. However, experiments with animal models now suggest that a significant amount is secreted directly into the intestines by a process known as trans-intestinal cholesterol efflux. How this occurs and its relevance to humans are under active investigation.

Certain bacterial species contain a 3β-hydroxysteroid:oxygen oxidoreductase (EC 1.1.3.6), commonly termed cholesterol oxidase, a flavoenzyme that catalyses the oxidation of cholesterol to cholest-5-en-3-one which is then rapidly isomerized to cholest-4-en-3-one as the first essential step in the more comprehensive catabolism of sterols. The enzyme is widespread in organisms that degrade organic wastes, but it also present in pathogenic organisms where it influences the virulence of infections (see below). In biotechnology, it has been used for the production of a number of steroids and it is employed clinically in the determination of cholesterol levels in serum.

### 4. Cholesterol Esters

**Cholesterol esters**, *i.e.* with long-chain fatty acids linked to the hydroxyl group, are much less polar than free cholesterol and appear to be the preferred form for transport in plasma and as a biologically inert storage (de-toxification) form. They do not contribute to membranes but are packed into intracellular lipid particles.

Because of the mechanism of synthesis (see below), plasma cholesterol esters tend to contain relatively high proportions of the unsaturated components typical of phosphatidylcholine (Table 1).
Arachidonic and “adrenic” (20:4(n-6)) acids can be especially abundant in cholesterol esters from the adrenal gland.

Cholesterol esters are major constituents of the adrenal glands, and they accumulate in the fatty lesions of atherosclerotic plaques. Esters of steroidal hormones are also present in the adrenal glands, where they are concentrated in cytosolic lipid droplets adjacent to the endoplasmic reticulum. 17β-Estradiol, the principal oestrogen in fertile women, is transported in lipoproteins in the form of a fatty acid ester.

In plasma, and the high-density lipoproteins (HDL) in particular, cholesterol esters are synthesised largely by transfer of fatty acids to cholesterol from position sn-2 of phosphatidylcholine (lecithin) catalysed by the enzyme lecithin:cholesterol acyl transferase (LCAT); the other product is 1-lysophosphatidylcholine (see also our webpage on lipoproteins). In fact, the reaction occurs in several steps. First, apoprotein A1 in the HDL acts to concentrate the lipid substrates near LCAT and present it in the optimal conformation. Then, cleavage of the sn-2 ester bond of phosphatidylcholine occurs via the phospholipase activity of LCAT with release of a fatty acyl moiety. This is transacylated to the sulfur atom of a cysteine residue forming a thioester, and ultimately it is donated to the 3β-hydroxyl group of cholesterol to form the cholesteryl ester.

It has been established that human LCAT is a relatively small glycoprotein with a polypeptide mass of 49 kDa, increased to about 60 kDa by four N-glycosylation and two O-glycosylation moieties. Most of the enzyme is produced in the liver and circulates in the blood stream bound reversibly to HDL, where it is activated by the main protein component of HDL, apolipoprotein A-I. As cholesterol esters accumulate in the core of the lipoprotein, cholesterol is removed from its surface thus promoting the flow of cholesterol from cell membranes into HDL. This in turn leads to morphological changes in HDL, which grow and become spherical.

Subsequently, cholesterol esters are transferred to the other lipoprotein fractions LDL and VLDL, a reaction catalysed by cholesteryl ester transfer protein. This process promotes the efflux of cholesterol from peripheral tissues (‘reverse cholesterol transport’), especially from macrophages in the arterial wall, for subsequent delivery to the liver. LCAT is often stated to be the main driving force behind this process, and it is of great importance for cholesterol homeostasis and a suggested target for therapeutic intervention against cardiovascular disease.

The stereo-specificity of LCAT changes with molecular species of phosphatidylcholine containing arachidonic or docosahexaenoic acids. 2-Lysophosphatidylcholines are then formed. This may be
especially important for the supply of these essential fatty acids to the brain, in that such lysolipids are believed to cross the blood-brain barrier more readily than the free acids.

In other animal tissues, a further enzyme acyl-CoA:cholesterol acyltransferase (ACAT) synthesises cholesterol esters from CoA esters of fatty acids and cholesterol. ACAT exists in two forms, both of which are intracellular enzymes found in the endoplasmic reticulum, and possess multiple hydrophobic regions predicted to function as trans-membrane domains. ACAT1 is present in many tissues, but especially in macrophages and adrenal and sebaceous glands, which store cholesterol esters in the form of cytoplasmic droplets. It is also responsible for the synthesis of cholesterol esters in arterial foam cells in human atherosclerotic lesions. ACAT2 is found only in the liver and small intestine, and it is believed to be involved in the supply of cholesterol esters to the nascent lipoproteins. Analogous enzymes are found in yeast.

Cholesterol ester hydrolases in animals liberate cholesterol and free fatty acids when required for membrane and lipoprotein formation, and they also provide cholesterol for hormone synthesis in adrenal cells. Many cholesterol ester hydrolases have been identified, including a carboxyl ester hydrolase, a lysosomal acid cholesterol ester lipase, hormone-sensitive lipase and hepatic cytosolic cholesterol ester hydrolase. These are located in many different tissues and organelles and have multiple functions. A neutral cholesterol ester hydrolase has received special study, as it involved in the removal of cholesterol esters from macrophages, so reducing the formation of foam cells and thence the development of fatty streaks within the arterial wall, a key event in the progression of atherosclerosis.

5. Other Animal Sterols

Cholesterol will oxidize slowly in tissues or foods to form a range of different products with additional hydroperoxy, epoxy, hydroxy or keto groups, and these can enter tissues via the diet. There is increasing interest in these from the standpoint of human health and nutrition, since accumulation of oxo-sterols in plasma is associated with inhibition of the biosynthesis of cholesterol and bile acids and with other abnormalities in plasma lipid metabolism. These and similar cholesterol oxides or oxysterols produced in tissues by specific microsomal or mitochondrial oxidations are discussed in a separate document on this web site.

There have been interesting speculations on the evolutionary significance of lanosterol biosynthesis. As oxygen is required, it cannot be produced by primitive organisms, hence its absence from prokaryotes. When sterols became available to eukaryotes, much greater possibilities opened for their continuing evolution. The production of cholesterol from lanosterol is then seen as ‘molecular streamlining’ by evolution, removing protruding methyl groups that hinder the interaction between sterols and phospholipids in membranes.

A number of other sterols occur in small amounts in tissues, most of which are intermediates in the pathway from lanosterol to cholesterol, though some of them have distinct functions in their own right. Lanosterol, the first sterol intermediate in the biosynthesis of cholesterol, was first found in wool wax, both in free and esterified form, and this is still the main commercial source. It is found at low levels only in most other animal tissues.

Further examples of animal sterols include 7-dehydrocholesterol (cholesta-5,7-dien-3β-ol) in the skin, which on irradiation with UV light is converted to vitamin D₃ (cholecalciferol). Desmosterol (5,24-cholestadien-3β-ol) may be involved in the process of myelination, as it is found in relative abundance in the brains of young animals but not in those of adults. It is also found in appreciable amounts in spermatozoa and astrocytes. There is a rare genetic disorder in which there is an impairment in the conversion of desmosterol to cholesterol, desmosterolosis, with serious consequences in terms of mental capacity. In human serum, the levels of lathosterol (5α-cholest-7-en-3β-ol) were found to be inversely related to the size of the bile acid pool, and in general the
concentration of serum lathosterol is strongly correlated with the cholesterol balance under most dietary conditions. The isomeric saturated sterols, cholestanol and coprastanol, which differ in the stereochemistry of the hydrogen atom on carbon 5, are formed by microbial biohydrogenation of cholesterol in the intestines, and together with cholesterol are the main sterols in faeces.

Marine invertebrates produce a large number of novel sterols, with both unusual nuclei and unconventional side-chains, some derived from cholesterol and others from plant sterols or alternative biosynthetic intermediates. For example, at least 80 distinct sterols have been isolated from echinoderms and 100 from sponges.

6. Cholesterol and Disease

Elevated cholesterol and cholesterol ester levels are associated with the pathogenesis of cardiovascular disease (atherosclerotic plaques, myocardial infarctions, and strokes), as is well known, but further discussion of such a complex nutritional topic is not possible here.

Cholelithiasis or the presence of 'stones' in the gallbladder or bile ducts, which consist largely of cholesterol (~85%), is one of the most prevalent and costly digestive diseases in developed countries. The primary cause is excessive excretion of cholesterol from the liver. Excess accumulation of cholesterol, associated with the metabolism of bis(monoacylglycerol)phosphate and causing disturbances in glycosphingolipid trafficking in cell membranes, is involved in the pathogenesis of Niemann-Pick C disease. In addition, deficiencies in cholesterol transport and metabolism are associated with many forms of neurodegeneration, including Alzheimer's disease and Huntington's disease.

It is less well known that a decrease in the concentration of cholesterol in the body can result in severe health problems, such as the recessive Smith-Lemli-Opitz syndrome in infants born with a decreased concentration of the enzyme 7-dihydrocholesterol reductase, and with symptoms varying from mild autism to severe mental and often fatal physical problems. The effects are due to a lack of cholesterol and the accumulation of 7-dehydrocholesterol and its 27-hydroxy metabolite, as brain tissue cannot utilize dietary cholesterol or that produced peripherally. In fact, eight different inherited disorders of cholesterol biosynthesis are recognized that lead to congenital abnormalities in those afflicted. It is evident that cholesterol plays a vital part in human embryogenesis and development.

When increased levels of sterols other than cholesterol are found in plasma, they usually serve as markers for abnormalities in lipid metabolism associated with disease states. For example, premature atherosclerosis and xanthomatosis occur in two rare lipid storage diseases, Cerebrotendinous xanthomatosis and sitosterolemia. In the former, cholestanol is present in all tissues, while in sitosterolemia, the dietary plant sterols campesterol and sitosterol accumulate in plasma and red blood cells. Inhibition of cholesterol biosynthesis may be associated with the appearance of some of the precursor sterols in the plasma.
In infections with *Mycobacterium tuberculosis*, the organism uses host cholesterol and cholest-5-en-3-one as the major carbon and energy source and thereby promotes persistent infection with appreciable effects on pathogenicity.

### 7. Analysis

With animal tissues, especially those of clinical importance such as plasma, the cholesterol content is often determined by using enzymatic methods from commercially available kits that are suited to routine analysis of large numbers of samples. For the total cholesterol content, it is necessary to hydrolyse the cholesterol ester fraction first, and this usually requires more vigorous conditions than with glycerolipids. For more accurate or detailed analysis of animal and plant sterols, a sterol fraction is first isolated from lipid extracts by thin-layer or column chromatography, following hydrolysis if necessary. Individual components can then be determined by gas chromatography in the presence of an internal standard (e.g. epicoprostanol or betulin), often after conversion to trimethylsilyl ether derivatives to give sharper peaks. Mass spectrometry may be required for identification of individual components. Sterol esters are transmethylated for GC analysis of the fatty acid components, although the reaction may again be much slower than with glycerolipids. Intact sterol esters are best analysed by reversed-phase HPLC.
